

# Molecular Dynamics

Another Brief Introduction

## What is MD?

- **Molecular dynamics is concerned with time dependent processes in molecular systems.**
- **Each dynamic process (i.e., motion) has a characteristic time-scale, amplitude and energy range.**
- **Can be applied to chemical, biochemical as well as solid-state systems**

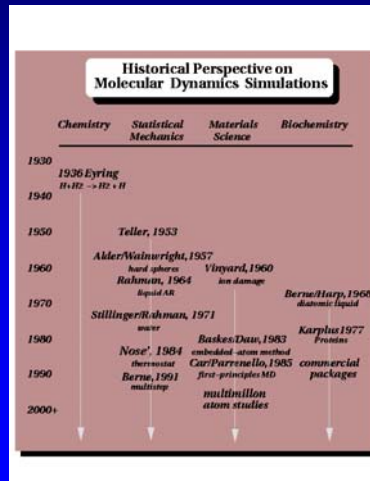

## Time scale in biosystems

Type of Motion	Example	Functionality Examples	Time and Amplitude Scales
<b>Local</b>	Atomic fluctuation Side chain motion	Ligand docking flexibility Temporal diffusion pathways	fs - ps ( $10^{-15}$ - $10^{-12}$ s) less than 1 Å
<b>Medium Scale</b>	Loop motion Terminal-arm motion Rigid-body motion (helices)	Active site conformation adaptation Binding specificity	ns - micro s ( $10^{-9}$ - $10^{-6}$ s) 1 - 5 Å
<b>Large Scale</b>	Domain motion Subunit motion	Hinge bending motion Allosteric transitions	micro s - ms ( $10^{-6}$ - $10^{-3}$ s) 5 - 10 Å
<b>Global</b>	Heix-coil transition Folding/unfolding Subunit association	Hormone activation Protein functionality	ms - h ( $10^{-3}$ - $10^4$ s) more than 5 Å

## What we can compute?

- ↗ How the structure of our system changes in time (conformational changes, phase transitions, etc...)
- ↗ Time dependent properties (diffusion)
- ↗ Thermodynamic properties (energy, heat capacity, pressure, etc....)

# Historical Perspective

# Some Remarks on Statistics

Our system is described by a classical **Hamiltonian**, a function of the coordinates **q** and momenta **p**.

$$H = H(q,p) = K(p) + V(q) = p^2/2m + V(q)$$

Each **state** of the system is thus characterized by the set (q,p); i.e., each state of the system is a point in the space defined by both coordinates and momenta. This space is called **Phase Space**.

## Boltzmann distribution

To compute the thermodynamics averages over a **canonic** ensemble (**N,V,T=constant**) it is necessary to know the probability for finding the system at each and every point (=state) in phase space.

$$P(\mathbf{q},\mathbf{p}) = e^{-H(\mathbf{q},\mathbf{p})/kT} / Z$$

**Z** = Canonical Partition Function

## Property average

If this **P** is known, an average of any of the system's dynamical variable  $A(\mathbf{q},\mathbf{p})$  can be calculated as **ensemble average**.

$$\langle A(\mathbf{q},\mathbf{p}) \rangle_Z = \int_V d\mathbf{q} \int_{-\infty}^{\infty} d\mathbf{p} P(\mathbf{q},\mathbf{p}) A(\mathbf{q},\mathbf{p})$$

Of course, it is necessary to know the Boltzmann probability for each and every state of the system simultaneously.

**Not an easy task at all!**

## Averages along a Trajectory

- An alternative averaging approach is to calculate averages along the motion of a single point through phase space. Such an average is called a **dynamic average**.
- The two averaging approaches are reciprocal:
  - Thermodynamic average** The average over **all** points in phase space at a **single** time.
  - Dynamic average** The average over a **single** points in phase space at **all** times.

## Equation of motion

- The motion of a single point through time is obtained by integrating the equation of motion of the system.
- Starting from the point  $\{q(0), p(0)\}$  the integration yields a **trajectory**
$$\{q(0), p(0)\} \rightarrow \{q(t), p(t)\}$$
- Averages of any dynamical variable  $A(q,p)$  can now be calculated along this **trajectory**:

$$\langle A(\mathbf{q}, \mathbf{p}) \rangle_T = \frac{1}{T} \int_0^T A(\mathbf{q}(t), \mathbf{p}(t)) dt$$

where  $T$  is the length of the simulation

## Ergodic Hypothesis

For an **infinitely long trajectory** the ensemble average and the dynamics average are **interchangeable**

$$\lim_{T \rightarrow \infty} \langle A(\mathbf{q}, \mathbf{p}) \rangle_T = \langle A(\mathbf{q}, \mathbf{p}) \rangle_Z$$

## Ergodic Hypothesis

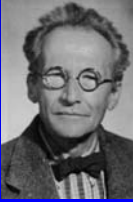

Two assumptions:

- ✓ The system is at a **stationary state** (e.g., at equilibrium).
- ✓ An infinitely long dynamic trajectory adequately covers **all of phase space**, so that the trajectory passes through all possible system states.

The application of "long" but *finite molecular dynamics simulations* assumes that the system is "ergodic" and that the finite simulation is "long enough".

# Equations of Motion

- ↗ Time-dependent Schrödinger's Equation (quantum)
- ↗ Newton's Equation (classical)
- ↗ Langevin's Equation (stochastic)

		
1887-1961	1643-1727	1872-1946

# Newton's Equation of Motion

- ↗ The Newton's second law of motion

$$\mathbf{F}_i = m_i \mathbf{a}_i = m \ddot{\mathbf{q}}_i = -\nabla_i V(\mathbf{q})$$

The force  $F_i$  is given as the derivative of the potential  $V$   
(as computed by any Molecular Mechanics approach!!)

## Hamilton equation

- Another, more basic, formulation of this equation can be given in terms of the system's Hamiltonian

$$H(\mathbf{q}, \mathbf{p}) = \sum_i \frac{1}{2m_i} p_i^2 + V(\mathbf{q})$$

The combination of Newton and Hamilton equation

$$\dot{q}_i = \frac{\partial H}{\partial p_i}$$
$$\dot{p}_i = -\frac{\partial H}{\partial q_i}$$

## Properties of Newton's equation

Some important properties of **Newton's equation** of motion are:

- ✓ Conservation of **energy**
- ✓ Conservation of **linear momentum**
- ✓ Conservation of **angular momentum**
- ✓ Time reversibility

These properties are used to test whether the numerical solution of the equation (i.e., the molecular dynamics simulation) is stable and reliable.

## Integration of Newton's equation

Solving Newton's equation of motion requires a numerical solution of the differential equation. This procedure is called **numeric integration**.  
Numeric integration involves several components:

### Integration Algorithms

- Verlet integrator
- Leap-Frog integrator
- Velocity Verlet integrator

### Initial conditions

- Initial coordinates
- Initial velocities

Mesaures for the stability of integrations

## Finite Difference Methods.

➤ They use the information available at **time  $t$**  to predict the system's coordinates and velocities at a **time  $t + dt$**

➤ based on a Taylor expansion of the position at time  $t + dt$

$$\mathbf{r}(t+dt) = \mathbf{r}(t) + \mathbf{v}(t) dt + \mathbf{a}(t) dt^2 / 2 + \dots$$

or in terms of the variables at step  $n$  and  $n+1$ .

$$\mathbf{r}_{n+1} = \mathbf{r}_n + \mathbf{v}_n dt + \mathbf{F}_n / 2m dt^2 + O(dt^3)$$

➤ The different integration algorithms vary **in the way** they implement this basic expansion.

## Verlet integrator

Two Taylor expansions, one forward and one backward

$$\begin{aligned}\mathbf{r}_{n+1} &= \mathbf{r}_n + \mathbf{v}_n dt + \mathbf{F}_n/2m dt^2 + \dots \\ \mathbf{r}_{n-1} &= \mathbf{r}_n - \mathbf{v}_n dt + \mathbf{F}_n/2m dt^2 - \dots\end{aligned}$$

These two expansions are then added to give the basic **Verlet integration** formalism:

$$\mathbf{r}_{n+1} = 2\mathbf{r}_n - \mathbf{r}_{n-1} + \mathbf{F}_n/m dt^2 + O(dt^4)$$

## Verlet integrator

### Advantages:

- Integration does not require the velocities, only position information is taken into account.
- Only a single force evaluation per integration cycle.
- This formulation is naturally reversible in time (a property of the equation of motion).

### Disadvantages:

- Introduces rather large numerical errors. An  $O(dt^2)$  term is added to an  $O(dt^0)$  term.
- The velocities, which are required for energy evaluation are calculated in an approximate manner only through the equation:  $\mathbf{v}_n = (\mathbf{r}_{n+1} - \mathbf{r}_{n-1})/2 dt$ .

## Leap Frog integrator

- Velocities are evaluated at the mid-point of the position evaluation and vice versa.

$$\begin{aligned} \mathbf{v}(t+dt/2) &= \mathbf{v}(t-dt/2) + \mathbf{a}(t) dt \\ \mathbf{r}(t+dt) &= \mathbf{r}(t) + \mathbf{v}(t+dt/2) dt \end{aligned}$$

Each integration cycle involves **three** steps:

- Calculate  $\mathbf{a}(t) dt$  (based on  $\mathbf{r}(t)$ )
- Calculate  $\mathbf{v}(t+dt/2)$
- Calculate  $\mathbf{r}(t+dt)$

The *instantaneous* velocity at time  $t$  is then calculated as

$$\mathbf{v}(t) = (\mathbf{v}(t+dt/2) + \mathbf{v}(t-dt/2)) / 2$$

## Leap Frog integrator

### Advantages:

- Improved evaluation of velocities.
  - Direct evaluation of velocities gives a useful handle for controlling the temperature in the simulation.
  - Reduces the numerical error problem of the Verlet algorithm. Here  $O(dt^1)$  terms are added to  $O(dt^0)$  terms.

### Disadvantages:

- The velocities at time  $t$  are still approximate.
- Computationally a little more expensive than Verlet.

## Initial Coordinates

- Initial coordinates are usually taken from **experiments** (x-ray, NMR).
- Since experimentally determined structures do not contain coordinates for hydrogen atoms, the first step is to **add hydrogen atoms** to the model.
- Initial **minimization** is essential to remove bad interactions from the initial structure.

## Initial Velocities

- Since the only information regarding the velocities is the desired **temperature** of the simulation, initial velocities ( $v_x, v_y, v_z$ ) are randomly assigned according to a **Maxwellian distribution**:

$$P(v_i)dv = (m/2\pi k_B T)^{1/2} \exp[-mv^2/2k_B T]$$

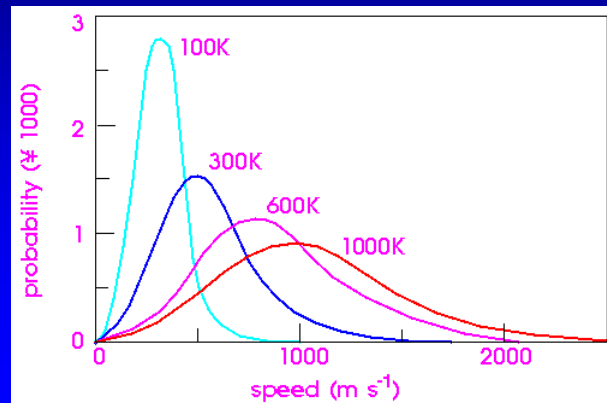

- The **instantaneous temperature** (necessary for heating the system) is defined based on **equipartition theorem** as

$$T(t) = (1/k_B(3N-n)) \sum_i (m_i v_i^2)$$

where  $N$  is the number of atoms, and  $n$  is the number of constrained degrees of freedom.

## Velocities and Temperature

Maxwell distribution of velocity of water at various temperatures

## Stability of integration

Any numerical integration is susceptible to errors and may become **unstable**. To ensure stability of the simulations the properties of Newton's equation of motion, representing an (N, V, E) ensemble, must be preserved

- ↗ *Conservation of energy*
- ↗ *Conservation of Linear Momentum*
- ↗ *Conservation of Angular Momentum*
- ↗ *Time reversibility*

# Stability of integration

**Conservation of energy**  
 Newton's equation preserves energy. Assuming the average energy fluctuations during a simulation at energy  $E$  are  $dE$ , a stable simulation will have:  

$$\log_{10}(dE/E) < -4$$

**Conservation of Linear Momentum**  
 Total linear momentum,  $\mathbf{P} = \sum_i \mathbf{P}_i$ , must be conserved

**Conservation of Angular Momentum**  
 Total angular momentum,  $\mathbf{L} = \sum_i \mathbf{q}_i \times \mathbf{P}_i$ , must be conserved

**Time reversibility**  
 Newton's equation is reversible in time. Numerical errors, however, hamper this reversibility introducing chaotic effects. Nonetheless, for short periods of time a stable integration should exhibit apparent temporal reversibility.

# MD begin

```
graph LR; A[Initial Coordinates] --> B[Minimize structure];
```

Cartesian, internal coordinates  
Or different file formats

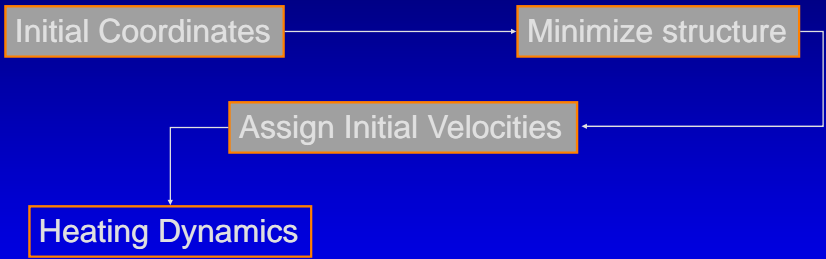

Methods: Newton-Raphson (block diagonal),  
steepest descent, conjugate gradient, others.

# MD Initial Velocities

```
graph LR; A[Initial Coordinates] --> B[Minimize structure]; B --> C[Assign Initial Velocities];
```

**Initial velocities at a low temperature are assigned to each atom and Newton's equations are integrated to propagate the system in time.**

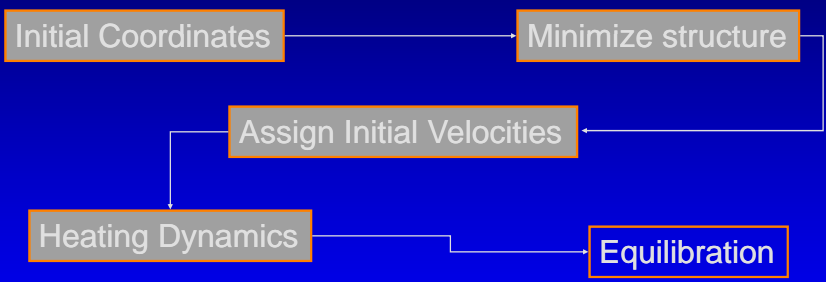

## MD Heating

```
graph TD; A[Initial Coordinates] --> B[Minimize structure]; B --> C[Assign Initial Velocities]; C --> D[Heating Dynamics];
```

new velocities are assigned at a slightly higher temperature and the simulation is allowed to continue. This is repeated until the desired temperature is reached

## MD Equilibration

```
graph TD; A[Initial Coordinates] --> B[Minimize structure]; B --> C[Assign Initial Velocities]; C --> D[Heating Dynamics]; D --> E[Equilibration];
```

Once the desired temperature is reached, the simulation of the system continues and several properties are monitored (the structure, the pressure, the temperature and the energy).

# MD Production

The "production" phase is runned for the time length desired (from several hundred ps to ns). The trajectories (coordinates and velocities) are collected

```
graph TD; A[Assign Initial Velocities] --> B[Heating Dynamics]; B --> C[Equilibration]; C --> D[Production];
```

The flowchart illustrates the MD Production process. It starts with 'Assign Initial Velocities', which leads to 'Heating Dynamics'. From 'Heating Dynamics', the process moves to 'Equilibration'. Finally, from 'Equilibration', the process proceeds to 'Production'.

# MD in practice

Using saved trajectories, thermodynamical properties (average values) are computed  
Structural (conformational) changes are observed

```
graph TD; A[Assign Initial Velocities] --> B[Heating Dynamics]; B --> C[Equilibration]; C --> D[Production]; D --> E[Analysis of trajectories];
```

The flowchart illustrates the MD in practice process. It starts with 'Assign Initial Velocities', which leads to 'Heating Dynamics'. From 'Heating Dynamics', the process moves to 'Equilibration'. From 'Equilibration', the process proceeds to 'Production'. Finally, from 'Production', the process moves to 'Analysis of trajectories'.

## Simulation parameters

The screenshot shows the 'Molecular Dynamics Options' dialog box. Annotations include:
 

- Time:** Points to the 'Times' section containing 'Heat time: 1 ps', 'Run time: 5 ps', 'Cool time: 0 ps', and 'Step size: 0.001 ps'.
- Temperature:** Points to the 'Temperature' section containing 'Starting temperature: 0 K', 'Simulation temperature: 298 K', 'Final temperature: 0 K', and 'Temperature step: 5 K'.
- NVT simulation:** Points to the 'Options' section where 'Constant temperature' is checked.

Starting value  $\phi=180^\circ$ ,  $\psi=180^\circ$  ( $\beta$ -sheet)

# Averages

E is conserved in average, oscillations depend on finite integration (same for T)

End of the heating (after 1ps)

$\beta$  sheet

$\alpha$  helix

The screenshot shows the 'Molecular Dynamics Averages' window with the following data points:
 

- ETOT: 52.76246
- TEMP: 406.0744
- Psi: 180
- T: 16.9957
- E\_tot: -179.3361

 The x-axis is labeled 'Time (ps)' and has a '6' at the end. The plot shows oscillations for Psi, T, and E\_tot, and a rising line for TEMP. Labels 'beta sheet' and 'alpha helix' point to specific features in the Psi and T plots respectively.
